A study was undertaken to determine the extent of change in bone mineral density (BMD) of the lumbar spine and proximal femur in elderly menopausal women. The prevalence of osteoporosis of these sites, defined as a BMD below 2.5 standard deviations (s.d.) below the mean for young women, was related to time since menopause and exogenous oestrogen replacement therapy (ERT). BMD was measured using dual energy X-ray absorptiometry (DEXA) in a sample of 53 women >50 years (mean age 65 years, range 50-84 years) who were randomly selected from a private general practice population. BMD was measured on two occasions with an interval of 4 weeks; 23 of these women were on continuous ERT (> or =5 years, mean treatment duration 8.5 years), and 30 women were not on ERT. There was no significant difference in BMD between those who were on ERT and those who were not when both were compared with young women. There was also no significant difference between the left and right BMD values of women. Neither the time since menopause nor the time on ERT was significantly related to BMD at either the lumbar spine or the proximal femur. In conclusion, in this elderly women population there were no significant reductions in BMD at the lumbar spine or proximal femur due to advanced age or long-term continuous ERT.1) The nucleus is the cell's control room. Without it, the cell cannot make new or repair itself. And because this control center is off-limits to the rest of the cell, it has to be well protected, and only a select few can gain entry. 2) Cancer cells that normally grow in a tumor have the same basic way of entering the cell's nucleus as highly controlled organisms do. They have to be knocked down or inactivated to gain entry, and they are recognized by proteins that normally guard the nucleus. Once inside, they can start to mess up the cell's basic operations by changing the cell's DNA. 3) The nucleus is also used by pathogens like viruses to make copies of themselves. Some viruses can literally enter the
